DISCLOSURES

2018 Revision - Writing Team

Kathleen Costello, MS, ANP-BC, MSCN – Nothing to disclose
Rosalind Kalb, PhD – Consultant: Sanofi-Genzyme and Novartis Pharmaceuticals

Reviewers

Jack Antel, MD – Advisory and/or data safety monitoring board: Biogen, Medday Laboratory support through McGill University: Mallinckrodt, Revalesio, Medday, Roche (Canada); Multiple Sclerosis Journal: Co-Editor for the Americas.

Brenda Banwell, MD – Non-remunerated consultant: Biogen, Novartis Pharmaceuticals, Sanofi US; Central MRI reviewer for prior trial for Novartis; Grant Support: National Multiple Sclerosis Society, Canadian Multiple Sclerosis Scientific Research Foundation.

Aliza Ben-Zacharia, DrNP, ANP, MSCN – Consultant: Biogen, EMD Serono, Novartis Pharmaceuticals, Genentech, Genzyme Corporation; Grant support: Biogen, Novartis Pharmaceuticals.

James Bowen, MD – Consultant: Biogen IDEC, EMD Serono, Genentech, Novartis; Speaker: Acorda Therapeutics, Biogen IDEC, EMD Serono, Genentech, Novartis, Teva Neuroscience; Grant support: Alexion, Alkermes, Biogen IDEC, Celgene, Genzyme, Genentech, Novartis, TG Therapeutics; Shareholder: Amgen.

Bruce Cohen, MD – Consultant: Biogen-Idec, EMD Serono, Celgene; Funded Institutional Research through Northwestern University, Novartis Pharmaceuticals, Genentech / Hoffman La Roche, MedDay.

Bruce Cree, MD, PhD – Consultant: Abbvie, Biogen, EMD Serono, Genzyme Corporation, Aventis, MedImmune, Novartis Pharmaceuticals, Teva Pharmaceuticals; Grant/research support (including clinical trials): Acorda Therapeutics, Avanir Pharmaceuticals, Biogen, EMD Serono, Hoffman La Roche, Novartis Pharmaceuticals.

Suhayl Dhib-Jalbut, MD – Grant support: Teva Pharmaceuticals, Biogen, Bayer.

David E. Jones, MD – Past consultant: Biogen, Genzyme Corporation, Novartis Pharmaceuticals; Past grant support: National Multiple Sclerosis Society, Biogen.

Daniel Kantor, MD – Consultant: Actelion Pharmaceuticals, Avanir Pharmaceuticals, Biogen, Celgene Corporation, Genzyme Corporation, Mylan, Novartis Pharmaceuticals, Osmotica Pharmaceutical; Speaker: Avanir Pharmaceuticals, Biogen, Genzyme Corporation, Novartis Pharmaceuticals; Grant support: Actelion Pharmaceuticals, Biogen, Genzyme Corporation, Novartis Pharmaceuticals.

Flavia Nelson, MD – Consultant for Advisory Boards or Speaker: Biogen, Novartis Pharmaceuticals, Teva Pharmaceuticals, Bayer HealthCare, Mallinckrodt, Genzyme Corporation; Grant support: National Institutes of Health.

Nancy Sicotte, MD – Grant support: National Multiple Sclerosis Society, Guthy-Jackson Charitable Foundation, Race to Erase MS, Patient-Centered Outcomes Research Institute (PCORI).

Principles and Current Evidence

A Consensus Paper by the Multiple Sclerosis Coalition

ABSTRACT

Purpose: The purpose of this paper, which was developed by the member organizations of the Multiple Sclerosis Coalition*, is to summarize current evidence about disease modification in multiple sclerosis (MS) and provide support for broad and sustained access to MS disease-modifying therapies for people with MS in the United States.

Development Process: The original writing and development team comprised of professional staff representing the Coalition organizations (Rosalind Kalb, Kathleen Costello, June Halper, Lisa Skutnik and Robert Rapp) developed a draft for review and input by nine external reviewers (Brenda Banwell, Aliza Ben-Zacharia, James Bowen, Bruce Cohen, Bruce Cree, Suhayl Dhib-Jalbut, Daniel Kantor, Flavia Nelson and Nancy Sicotte). The reviewers, selected for their experience and expertise in MS clinical care and research, were charged with ensuring the accuracy, completeness and fair balance of the content. The revised paper was then submitted for review by the medical advisors of the Coalition member organizations.

The final paper, incorporating feedback from these advisors, was endorsed by all Coalition members, and subsequently by Americas Committee for Treatment and Research in Multiple Sclerosis (ACTRIMS), and published in November 2014.

Updates with Reviews by External Reviewers and ACTRIMS for their Endorsement:

- March 2015
- July 2016
- March 2017
- September 2018

Conclusions: Based on a comprehensive review of the current evidence, the Multiple Sclerosis Coalition* states the following:

Treatment Considerations:

- Initiation of treatment with an FDA-approved disease-modifying therapy is recommended:
  - As soon as possible following a diagnosis of relapsing multiple sclerosis, regardless of the person’s age
  - For individuals with primary progressive multiple sclerosis, with an agent approved for this phenotype
  - For individuals with a first clinical event and MRI features consistent with MS in whom other possible causes have been excluded
  - For individuals with progressive MS who continue to demonstrate clinical relapses and/or demonstrate inflammatory activity
- Clinicians should consider prescribing a high efficacy medication such as alemtuzumab, fingolimod, ocrelizumab or natalizumab for newly-diagnosed individuals with highly active MS.

*The Multiple Sclerosis Coalition was founded in 2005 to increase opportunities for cooperation and provide greater opportunity to leverage the effective use of resources for the benefit of the MS community. Member organizations include Accelerated Cure, Can Do Multiple Sclerosis, Consortium of Multiple Sclerosis Centers, International Organization of Multiple Sclerosis Nurses, Multiple Sclerosis Association of America, Multiple Sclerosis Foundation, National Multiple Sclerosis Society and United Spinal Association. MS Views and News serves as an affiliate member (since 2015).
Clinicians should also consider prescribing a high efficacy medication for individuals who have breakthrough activity on another disease-modifying therapy, regardless of the number of previously used agents.

Treatment with a given disease-modifying medication should be continued indefinitely unless any of the following occur – in which case an alternative disease-modifying therapy should be considered:
- Sub-optimal treatment response as determined by the individual and his or her treating clinician
- Intolerable side effects, including significant laboratory abnormalities
- Inadequate adherence to the treatment regimen
- Availability of a more appropriate treatment option
- The healthcare provider and patient determine that the benefits no longer outweigh the risks

Movement from one disease-modifying therapy to another should occur only for medically appropriate reasons as determined by the treating clinician and patient.

When evidence of additional clinical or MRI activity while on consistent treatment suggests a sub-optimal response, an alternative regimen (e.g., different mechanism of action) should be considered to optimize therapeutic benefit.

The factors affecting choice of therapy at any point in the disease course are complex and most appropriately analyzed and addressed through a shared decision-making process between the individual and his or her treating clinician. Neither an arbitrary restriction of choice nor a mandatory escalation therapy approach is supported by data.

Access Considerations:

- Due to significant variability in the MS population, people with MS and their treating clinicians require access to the full range of treatment options for several reasons:
  - Different mechanisms of action allow for treatment change in the event of a sub-optimal response.
  - Potential contraindications limit options for some individuals.
  - Risk tolerance varies among people with MS and their treating clinicians.
  - Route of delivery, frequency of dosing and side effects may affect adherence and quality of life.
  - Individual differences related to tolerability and adherence may necessitate access to different medications within the same class.
  - Pregnancy and breastfeeding limit the available options.

- Individuals’ access to treatment should not be limited by their frequency of relapses, level of disability, or personal characteristics such as age, sex or ethnicity.

- Absence of relapses while on treatment is a characteristic of treatment effectiveness and should not be considered a justification for discontinuation of treatment.

- Treatment should not be withheld during determination of coverage by payers as this puts the patient at risk for recurrent disease activity.

THE MULTIPLE SCLEROSIS COALITION .................................................................................................. 70
INTRODUCTION

Multiple sclerosis (MS) is a disorder of the central nervous system (CNS) characterized by inflammation, demyelination and degenerative changes. Most people with MS experience relapses and remissions of neurological symptoms, particularly early in the disease, and clinical events are usually associated with areas of CNS inflammation.\(^1\) Gradual worsening or progression, with or without subsequent acute attacks of inflammation or radiological activity, may take place early, but usually becomes more prominent over time.\(^5\) While traditionally viewed as a disease of only CNS white matter, more advanced imaging techniques have demonstrated significant early and ongoing CNS gray matter damage as well.\(^6\)–\(^9\)

Those diagnosed with MS may have many fluctuating and disabling symptoms (including, but not limited to, fatigue, impaired mobility, mood and cognitive changes, pain and other sensory problems, visual disturbances and elimination dysfunction), resulting in a significant impact on quality of life for patients and their families. As the most common non-traumatic, disabling neurologic disorder of young adults – a group not typically faced with a chronic disease – MS threatens personal autonomy, independence, dignity and life planning,\(^10\) potentially limiting the achievement of life goals. The free-spirit spontaneity so highly valued by young adults needs to shift to purposeful planning considering the challenges posed by fluctuations in function and an uncertain future. The patient’s self-definition, roles and relationships may be co-opted by the need to adapt to an unpredictable disease requiring frequent healthcare visits, periodic testing and costly medications.

Compared to patients with other chronic diseases, those diagnosed with MS have diminished ratings in health, vitality and physical functions, and experience limitations in social roles.\(^11\) Productivity and participation are affected for many, including early departure from the workforce and inability to fulfill household responsibilities.\(^12\) In a study of disease burden, based on data from the Medical Expenditure Panel Survey (MEPS) – a public access, large-scale database that links direct cost information with information on productivity and health-related quality of life – Campbell and colleagues found that annual direct healthcare costs for people with MS were $24,327 higher than for the general population. In addition, people with MS had a significantly higher risk of being unemployed, spent significantly more time in bed, and lost on average 10.04 quality-adjusted life years compared to the general population. In a systematic review of 48 cost-of-illness studies, medications were the main expense for those with milder disease while loss of income combined with informal care needs contributed the biggest costs for those with more advanced disease.\(^13\)–\(^14\) Furthermore, registry studies specific to MS and large population cohort studies of individuals untreated with a disease-modifying therapy have demonstrated a reduced life expectancy of 8-12 years.\(^15\)

Epidemiology, Demographics, Disease Course

It is estimated that there are more than two million people with MS worldwide\(^16\) with the number approaching 1,000,000 in the United States.\(^17\) Women are affected at least three times more than men\(^18\) and Caucasians are affected more than other racial groups.\(^19\) However, a recent study\(^20\) suggested that African-American women have a higher than previously reported risk of developing MS and several studies have suggested that African-Americans\(^21\)–\(^25\) and Hispanics\(^26\)–\(^30\) may have a more active, rapidly progressive disease course. MS is typically diagnosed in early adulthood, but the age range for disease onset is wide with both pediatric cases and new onset in older adults. Historically, a geographic gradient has been observed with a higher incidence of MS with increased distance from the equator.\(^31\)–\(^32\) However, some recent studies have not demonstrated the same latitudinal gradient,\(^33\)\(^34\) suggesting either a change in regional risk determinants for MS or a broadening of the prevalence and recognition of MS worldwide.

The course of MS varies. However, 85-90 percent of individuals demonstrate a relapsing pattern at onset, which transitions over time in most untreated patients to a pattern of progressive worsening with few or no relapses or MRI activity (secondary progressive MS). Approximately 10-15 percent present with a relatively steady progression of symptoms over time (primary progressive MS), of which some will subsequently experience inflammatory activity by clinical or MRI criteria.\(^1\)\(^2\) This primary progressive
course is generally diagnosed at an older age, is typically spinal cord-predominant, and is distributed more equally in men and women. The 2013 revisions to the MS clinical course descriptions further characterize relapsing and progressive MS as active (new relapses and/or new MRI activity) or not active, and worsening (disability progression) or stable based on clinical and MRI criteria. (See Appendix A for a full description of the revised disease courses).

Prior to the era of disease modifying treatments, approximately half of patients diagnosed with relapsing MS would progress to secondary progressive MS by 10 years, and 80-90 percent would do so by 25 years. Approximately half of patients would no longer be able to walk unaided by 15 years. More recent data in the era of disease-modifying therapy demonstrate that the percentage of patients with relapsing MS who develop secondary-progressive MS may now be 15-30 percent.

**Inflammation and CNS Damage**

At present, much of the CNS damage in MS is believed to result from an immune-mediated process. Although the cause of the immunological changes is not completely understood, Vitamin-D deficiency, which is commonly present in MS, is thought to enhance inflammation. Gut dysbiosis is also thought to contribute to MS pathogenesis through mechanisms that have yet to be defined.

This immune-mediated process includes components of the innate immune system (including macrophages, natural killer cells and others) as well as adaptive immune system activation of certain lymphocyte populations in peripheral lymphoid organs. CD4+ lymphocytes, CD8+ lymphocytes and B lymphocytes are activated in the peripheral lymph tissues. Antigen presentation to naïve CD4+ lymphocytes causes differentiation into various T lymphocyte cell populations, depending on the antigen presented, the cytokine environment and the presence of co-stimulatory molecules. The T lymphocyte cell populations include Th1 and Th17 lymphocytes (which are associated with a variety of inflammatory cytokines that activate macrophages and opsonizing antibodies) and Th2 lymphocytes and T regulatory cells (which drive humoral immunity or secrete anti-inflammatory cytokines). In people with MS, there is a bias towards a Th1 and Th17 environment with T regulatory dysfunction that allows inflammation to predominate. Secreted cytokines and matrix metalloproteinases disrupt the blood-brain barrier. This disruption, along with up-regulation of adhesion molecules on blood vessel endothelium and activation of T cells, allows T cells to gain entry into the CNS, where additional activation takes place that initiates a damaging inflammatory cascade of events within the CNS. Multiple inflammatory cells become involved, including microglial cells and macrophages. In addition to CD4+ activation, CD8+ T lymphocytes have also been identified as important contributors to damaging CNS inflammation, and in fact have been identified by numerous researchers as the predominant T cell present in active MS lesions. Mechanisms of remission and recovery are not fully understood but are believed to be mediated by the expansion of regulatory cells that downregulate inflammation such as Foxp3 positive cells, Tr1 (IL-10 secreting), Th3 (TGF-B secreting) and CD56bright NK cells. Proliferation of progenitor oligodendroglia and remyelination contribute to recovery at least in the early stages of the disease.

Further contributions to CNS damage in MS are associated with B cell activation. B cells function as antigen presenting cells and also produce antibodies and pro-inflammatory cytokines that have damaging effects on myelin, oligodendrocytes and other neuronal structures. The importance of B cells in MS immunopathogenesis is supported by the consistent finding of oligoclonal immunoglobulins in the CSF; the successful clinical trials with B cell depleting monoclonal antibodies (rituximab and more recently ocrelizumab) that showed efficacy in RRMS and a subset of patients with primary progressive disease; and the presence of B-cell enriched meningeal follicles in progressive patients.

Recent studies have also revealed that mitochondrial damage, possibly as a result of free radical, reactive oxygen species and nitrous oxide (NO) activity associated with activated microglia, and iron deposition occur in MS, and make a significant contribution to demyelination and oligodendrocyte damage.
Immune-mediated responses leading to inflammation, with secretion of inflammatory cytokines, activation of microglia, T and B cell activity, mitochondrial damage and inadequate regulatory function, are believed to be at least partially responsible for demyelination, oligodendrocyte loss and axonal damage – all of which occur in acute inflammatory lesions.\textsuperscript{51,52} Axons that survive acute attacks may require increased energy to compensate for damage leading to later death from metabolic stress.\textsuperscript{51} Axonal loss, which correlates best with disability, begins early in the disease process as evidenced by identified pathological changes as well as imaging studies.\textsuperscript{52,53}

**Blood Brain Barrier**
OVERVIEW OF FDA-APPROVED DISEASE-MODIFYING AGENTS IN MS

Currently, 15 disease-modifying agents are approved by the U.S. Food and Drug Administration (FDA).

Note: Zinbryta (daclizumab) was approved to treat relapsing forms of MS in 2016 and voluntarily withdrawn from the market in 2018.

Table 1: FDA-approved disease-modifying agents in MS (in alphabetical order by route of administration).

Refer to the full FDA prescribing information for each medication for contraindications, side effects, warnings and precautions, and pre-treatment recommendations and procedures.

FDA pregnancy categories were replaced by pregnancy guidelines in June 2015 to make them more meaningful for patients and providers, and to allow for patient-specific counseling and informed decision-making (see p. 29).

| **Glatiramer acetate**<sup>54,55</sup>  
(Copaxone®; Glatopa®- therapeutic equivalent; Glatiramer acetate injection)  
20mg SC daily or 40mg SC three times weekly  
Indication: relapsing forms of MS  
Pregnancy Cat: B | Mechanism of action in MS is not fully understood. Subsequent research suggests:  
-Promotes differentiation in Th2 and T-reg cells leading to bystander suppression in CNS.<sup>56</sup>  
-Increases release of neurotrophic factors from immune cells.<sup>56</sup>  
-Deletion of myelin-reactive T cells.<sup>56</sup> | -Injection-site reactions  
-Lipoatrophy  
-Vasodilation, rash, dyspnea  
-Chest pain  
-Lymphadenopathy<sup>56</sup> | -Immediate transient post-injection reaction (flushing, chest pain, palpitations, anxiety, dyspnea, throat constriction, and/or urticaria)  
-Lipoatrophy and skin necrosis  
-Potential effects on immune response |
| **Interferon beta-1a**<sup>57</sup>  
(Avonex®)  
30mcg IM weekly  
Indication: relapsing forms of MS  
Pregnancy Cat: C | Mechanism of action in MS is unknown. Subsequent research suggests:  
-Promotes shift from Th1-Th2.  
-Reduces trafficking across BBB.<sup>56,59</sup>  
-Restores T-reg cells.<sup>56</sup>  
-Inhibits antigen presentation.<sup>56</sup>  
-Enhances apoptosis of autoreactive T-cells.<sup>56</sup> | -Flu-like symptoms  
-Depression  
-Elevated hepatic transaminases | -Depression, suicide and/or psychosis  
-Hepatic injury  
-Anaphylaxis and other allergic reactions  
-CHF  
-Lower peripheral blood counts  
-Seizures  
-Other autoimmune disorders  
-Thrombotic microangiopathy |
| **Interferon beta-1b**<sup>60</sup>  
(Rebif®)  
22mcg or 44mcg SC three times weekly  
Indication: relapsing forms of MS  
Pregnancy Cat: C | Same as above | -Injection-site reactions  
-Flu-like symptoms  
-Abdominal pain  
-Depression  
-Elevated hepatic transaminases  
-hematologic abnormalities | -Depression and/or suicide  
-Hepatic injury  
-Anaphylaxis and other allergic reactions  
-Injection-site reactions including necrosis  
-Lower peripheral blood counts  
-Seizures  
-Thrombotic microangiopathy |
| **Interferon beta-1b**<sup>61,62</sup>  
(Betaser®) (Extavia®)  
0.25mg SC every other day  
Indication: relapsing forms of MS  
Pregnancy Cat: C | Same as above | -Flu-like symptoms  
-Injection-site reactions  
-Elevated hepatic transaminases  
-Low WBC  
-See warnings<sup>61,62</sup> | -Hepatic injury  
-Anaphylaxis and other allergic reactions  
-Depression and/or suicide  
-CHF  
-Injection-site necrosis  
-Low WBC  
-Flu-like symptoms  
-Seizures  
-Thrombotic microangiopathy |

| dimethyl fumarate (Tecfidera®) | Mechanism of action in MS is unknown. It has been shown to promote anti-inflammatory and cytoprotective activities mediated by Nrf2 pathway. | - Anaphylaxis and angioedema  
- Progressive multifocal leukoencephalopathy (PML)  
- Lymphopenia  
- Elevated AST  
- Liver injury  
- Flushing  
- GI symptoms  
- Pruritus  | - Anaphylaxis and angioedema  
- PML  
- Lymphopenia (consider discontinuing treatment in patients with persistent lymphopenia (<500) lasting over 6 months)  
- Flushing  
- Liver injury |  |
| 240mg PO twice daily  
Indication: relapsing forms of MS  
Pregnancy Cat: C |  |  |  |

| fingolimod (Gilenya®) | Mechanism of action in MS most likely involves blocking of S1P receptor on lymphocytes thus preventing their egress from secondary lymph organs. | - Headache  
- Influenza  
- Diarrhea  
- Back pain  
- Elevated hepatic enzymes  
- Cough  
- Bradycardia following first dose  
- Macular edema  
- Lymphopenia  
- Bronchitis/pneumonia  | - Bradyarrhythmia and/or atrioventricular block following first dose  
- Risk of infections including serious infections – monitor for infection during treatment and for 2 months after d/c  
- Avoid live attenuated vaccines during treatment and for 2 months after d/c  
- PML  
- Cryptococcal infections  
- Macular edema  
- Posterior reversible encephalopathy syndrome (PRES)  
- Low pulmonary function tests (FEV1)  
- Hepatic injury  
- Increased BP  
- Basal cell carcinoma  
- Fetal risk: women should avoid conception for two months after treatment d/c  
- Decreased lymphocyte counts for 2 months after drug d/c  
- Severe increase in disability after stopping treatment |  |
| 0.5mg PO daily for patients weighing >40kg  
0.25mg PO daily for patients weighing <40kg  
Indication: relapsing forms of MS in patients 10 years of age and older

| **ocrelizumab**<sup>76</sup>  
(Ocrevus™) | The precise mechanism of action is not known but is presumed to involve binding to CD20, a cell surface antigen on pre-B and mature B lymphocytes, causing antibody-dependent and complement-mediated cytolysis. | -Infusion reactions (potentially life-threatening)  
-Infections  
-Possible increased risk of malignancies (including breast cancer, which occurred in 6 of 781 treated patients and no placebo patients) | -Infusion reactions that can include: pruritis, rash, urticaria, erythema, bronchospasm, throat irritation, oropharyngeal pain, dyspnea, pharyngeal or laryngeal edema, flushing, hypotension, pyrexia, fatigue, headache, dizziness, nausea, tachycardia. Premedication and observation period recommended.  
-Infections, including respiratory tract infections, herpes and potentially PML  
-Hepatitis B reactivation  
-Possible increased immunosuppressive effect if immunosuppressant used prior to or after ocrelizumab  
-Malignancies  
-Administer all vaccinations at least 6 weeks prior to administration of ocrelizumab; no live-attenuated or live vaccines during treatment and until B-cell repletion |
DISEASE-MODIFYING THERAPY CONSIDERATIONS

Several important themes emerge from the growing body of evidence in MS therapeutics:

1) Early successful control of disease activity – including the reduction of clinical and sub-clinical attacks and the delay of the progressive phase of the disease – appears to play a key role in preventing accumulation of disability, prolonging the ability of people with MS to remain active and engaged, and protecting quality of life.

2) Physical impairments comprise only one aspect of disability that results from early disease activity and disease progression. Cognitive impairment and fatigue are common early in the disease process and cause disability independent of physical function. In addition, common physical comorbidities in MS are associated with persistent fatigue, and depression at baseline is associated with worsening fatigue over time.

3) Prognosis at the individual level remains highly variable and unpredictable.

4) Adherence to treatment is important to efficacy and may be impacted by a wide range of factors requiring early identification and intervention.

In 2018, the American Academy of Neurology published the Practice Guideline: Disease-Modifying Therapies for Adults with Multiple Sclerosis. The Guideline provides evidence-based recommendations for starting, switching and stopping disease-modifying agents. These recommendations consider the patient’s perspective in the complex decision-making process in order to enhance shared decision-making. Refer to the full Guideline at AAN.com/guidelines. In the same year, ECTRIMS and the EAN (European Academy of Neurology) published the ECTRIMS/EAN Guideline on the Pharmacological Treatment of People with Multiple Sclerosis. Refer to this guideline for additional expert recommendations for the adult MS population.

Disease Factors Highlighting the Importance of Early Treatment

The goal of disease-modifying treatment is to reduce the early clinical and sub-clinical disease activity that is thought to contribute to long-term disability.

The following points highlight the importance of early treatment:

- **Neuroinflammation and neurodegeneration occur simultaneously throughout the disease course**

  It had long been thought that MS was characterized by early inflammatory damage followed by later neurodegeneration. However, a growing body of evidence demonstrates that inflammation and degeneration occur simultaneously, that clinical recovery reflects reserve capacity, and that subclinical damage ultimately leads to permanent clinical deficits. Evidence also indicates that inflammation contributes to worsening progression, even if not the sole cause. Hence, inflammation and degeneration are inter-related rather than independent. Additional evidence to support neuroinflammatory and neurodegenerative changes throughout the disease process includes:
- Early in MS, new MRI activity, evidenced by gadolinium enhancement, occurs approximately 7-10 times more frequently than clinical activity. 
- Early in the disease process, advanced MRI techniques demonstrate abnormalities in normal appearing white matter as well as gray matter in the absence of focal lesions seen on conventional imaging. 
- Brain atrophy has been identified in early MS, even at the time of the first clinical attack.
- Atrophy has been seen in radiologically isolated syndrome (RIS – the incidental finding of MS-like lesions in the absence of known clinical relapses). 
- Inflammatory activity has been observed in patients with both relapsing and progressive forms of the disease.

Given the evidence that inflammation and neurodegeneration are interrelated and occur throughout the disease process, prompt initiation and optimization of treatment help to minimize early inflammation and axonal damage.

- **Individuals with a first clinical event accompanied by MRI findings consistent with MS have a high probability of experiencing further clinical disease activity**

The term “clinically-isolated syndrome” (CIS) has been used to describe a first episode of neurologic symptoms that lasts at least 24 hours and is caused by inflammation and demyelination in one or more sites in the CNS.

Eighty percent of the placebo-treated patients in the four published phase III CIS trials with injectable medications had subsequent clinical events, which was defined at the time as conversion to clinically-definite MS (CDMS). Follow-up data for these patients indicated a variable disease course, with approximately one-third having minimal clinical relapses and physical disability after 15-20 years, but 42-50 percent converting to secondary progressive (SPMS) with increasing disability. Furthermore, baseline MRI findings in CIS predicted the development of definite MS as defined at the time. Lesion volume and the rate of lesion development earlier in the disease course were found to correlate with disability after 20 years.

The importance of delaying and limiting additional relapses early in the disease process was further supported by a CIS trial with teriflunomide published in 2014.

The 2017 revision of the McDonald diagnostic criteria (See Appendix B) facilitated an earlier diagnosis of MS based on a first clinical event, and MRI findings demonstrating dissemination in space and time. Using these newer criteria, many individuals in the early CIS trials would already have been diagnosed with MS. Although the term “CIS” may be nearly obsolete today, the importance of delaying and limiting additional relapses early in the disease process remains clear.

Based on data from the published CIS trials, prompt identification of early relapsing patients with little or no disability is essential in order to achieve the best possible short- and long-term outcomes.

- **Individuals with RIS are at significant risk for subsequent clinical disease activity**

Although RIS is not currently recognized as a separate MS phenotype (see Appendix A), emerging data suggest that within five years, 30 percent of patients with an RIS presentation develop a symptomatic clinical event and two-thirds demonstrate new lesions on MRI. In these studies, younger individuals with RIS and spinal cord lesions, CSF inflammatory markers, abnormal visual evoked potentials, and/or contrast enhancing MRI lesions were more likely to have a subsequent symptomatic CNS demyelinating event. Notably, nearly 10 percent of people with RIS were found to have a progressive course, thereby fulfilling criteria for PPMS. And, 20-30 percent of RIS patients demonstrate cognitive changes similar to those seen in patients with RRMS. In their
review of these data, Lebrun and colleagues\textsuperscript{96} as well as Labiano-Fontcuberta and Benito-Leon\textsuperscript{97} recommended further study of RIS before a general recommendation for treatment can be made.

- **Early disease activity and disease course appear to impact long-term disability**

  Debate is ongoing about the ways and extent to which early disease activity impacts long-term disability.

  - Some evidence suggests that early disability progression as measured by the Expanded Disability Status Scale (EDSS)\textsuperscript{106} is the result of residual impairments from partially-resolved relapses.\textsuperscript{80,107–109} Natural history studies suggest that relapses in the first two years of disease impact early progression,\textsuperscript{110} with the impact of early relapses diminishing later in the disease course.\textsuperscript{111} However, Jokubaitis and colleagues found the effect of relapses on disability accrual in a treated cohort of patients to be significant, even for relapses that occurred ≥14 years after disease onset, although earlier relapses had the greatest impact.\textsuperscript{112}

  - The onset and evolution of secondary progressive MS (SPMS) – in which inflammatory attacks decrease – also appear to have an important association with long-term disability.\textsuperscript{113} From this perspective, earlier SPMS onset is a primary predictor of disability, which means that a person’s prognosis is essentially determined before progressive symptoms become predominant.

  - Data from both early and late in the disease course highlight the impact of early disease activity on long-term outcomes. In patients identified as having CIS, Brex and colleagues\textsuperscript{114} found that increases in lesion volume on MRI in the first five years of the disease correlate with the degree of long-term disability. Data from the 16-year follow-up cohort study of the pivotal trial of interferon beta-1b suggest that long-term physical and cognitive outcomes may be determined early in the disease.\textsuperscript{115}

  Given the medications that are currently available – all of which primarily target inflammation – the optimal window for impacting long-term disability is during the early relapsing phase of the disease, with the goal being to slow the accumulation of lesion volume, decrease the number of relapses, and prevent disability from both unresolved relapses and disease progression.\textsuperscript{80}

- **Cognitive changes, depression and fatigue occur very early in the disease process**

  It is currently recognized that approximately 60-65 percent of people with MS will experience cognitive impairment;\textsuperscript{116} 36-54 percent will experience a major depressive disorder;\textsuperscript{117} and up to 92 percent will experience significant fatigue,\textsuperscript{118} contributing to increased disability and reduction in quality of life.

  - Evidence is accumulating that approximately 20-30 percent of people with a first clinical event have already experienced cognitive changes.\textsuperscript{119–125} In fact, cognitive deficits similar to those seen in RRMS have been found in 20-30 percent of individuals with RIS.\textsuperscript{103–105}

  - Some studies suggest that cognitive deficits may precede the onset of MS by as much as 1.2 years.\textsuperscript{119} More specifically, verbal deficits have been shown to occur early and may predict the presence of cognitive impairment in people with a first clinical event.\textsuperscript{121}

  - Early cognitive changes are also known to progress, even in people with little or no physical changes,\textsuperscript{124} and deterioration can be expected over a three-year period in approximately one-third of people with short disease duration.\textsuperscript{126}

  - Cognitive deficits are detected in approximately 30 percent of pediatric MS patients.\textsuperscript{127–129}

  - Depression and fatigue have been found along with cognitive deficits in early MS, with each having a significant impact on quality of life, employment and other important activities of daily life\textsuperscript{130,131} — findings that highlight the importance of early treatment to help preserve people’s ability to remain optimally engaged in everyday activities, including employment and social interactions.\textsuperscript{81,124}
• So-called “benign MS” may not be benign for many people

The most common working definition of “benign MS” – an Expanded Disability Status Score (EDSS) \( \leq 3 \) at 10 years\textsuperscript{132} – is highly weighted for patients’ motor abilities and fails to capture non-motor components of the disease, particularly mood, cognition and fatigue.

- In one cohort of individuals meeting the criteria for “benign MS,” 45 percent were found to be cognitively impaired, 49 percent had significant fatigue, and 54 percent were found to be depressed.\textsuperscript{133}
- In another cohort of people with “benign MS” followed for 10.9 additional years, 81 percent (35/43) developed higher EDSS scores, cognitive impairment, pain and/or depression, as well as a significant increase in new or enlarging T2 lesions and gadolinium (Gd)-enhancing lesions over time.\textsuperscript{134}
- Sayao and colleagues evaluated disease status in a “benign MS” cohort after 20 years and found that while 51 percent remained benign, 21 percent had progressed to EDSS \( \geq 6 \) and 23 percent had converted to SPMS. The authors concluded that appropriate criteria for determining which individuals will have a truly benign course of the disease have not yet been identified.\textsuperscript{135}

Based on these findings, benign MS can only be diagnosed retrospectively, after a minimum of 20 years. Therefore, the term should only be applied – if at all – in retrospect, and any decision to delay treatment for a given individual needs to take into account non-motor as well as motor variables.\textsuperscript{136}

Evidence Demonstrating the Impact of Treatment Following a First Clinical Event

Although none of the available treatments are fully effective in stopping MS disease activity or disease progression, evidence points to the favorable impact of treatment following a first clinical event:

Delaying conversion to clinically-definite MS (CDMS)

Each of four published placebo-controlled phase III trials of injectable medications\textsuperscript{88-91} in patients with clinically-isolated syndrome (CIS),\textsuperscript{88-91} as well as the CIS trial with teriflunomide,\textsuperscript{94} demonstrated that early treatment successfully delayed conversion to CDMS (as defined at the time of these trials) by 37-45 percent at two to three years compared with placebo.

The eight-year, open-label follow-up of the early intervention study with interferon beta-1b, which compared the immediate treatment group with the delayed treatment (placebo) group, further demonstrated a reduced risk of CDMS and longer median time to CDMS in the early treatment group,\textsuperscript{137} although the greatest differences occurred in the first year of treatment. A follow-up open-label phase of the early intervention study with glatiramer acetate demonstrated a reduced risk of CDMS and a delay in conversion to CDMS in the immediate treatment group as compared with the delayed treatment (placebo) group.\textsuperscript{138}

Reducing brain atrophy and disability worsening

In meta-analyses of CIS treatment trials, each of two years duration (ETOMS, PreCISE, TOPIC)\textsuperscript{88,94,139} the rate of brain atrophy was attenuated after one year of treatment.\textsuperscript{140}

In a large cohort of CIS patients, disease-modifying treatments reduced 3-month confirmed and 12-month sustained disability worsening.\textsuperscript{141}
Evidence Demonstrating the Impact of Treatment on Relapsing MS

Each of the approved disease-modifying therapies has been shown to provide significant benefits in relapsing forms of MS. *Due to differences in patient cohorts, trial designs and outcome measures, as well as changes in diagnostic criteria, these data should not be used to compare efficacy between specific agents except where they are compared in the same trial.*

Impact on clinical outcomes (relapse rates and disability progression)

Table 2: Disease-modifying therapies: pivotal trial data on relapse rate and disability progression (in alphabetical order within route of administration).* Primary outcomes are identified with a +.

N.S.= Not Significant;

* Comparison across clinical trials is impossible due to differences in patient populations, diagnostic definitions, primary and secondary endpoints and outcome metrics.

MS relapses produce a measurable and sustained impact on disability.109,112 While it remains unclear the extent to which reducing relapses impacts long-term disability levels, it is evident that relapse reduction translates into increased comfort and quality of life, fewer days lost from work and other essential activities of daily life, and reduces the risk of residual deficits.109,158

Impact on MRI parameters

MRI is a sensitive indicator of disease activity in relapsing forms of MS that can detect new lesions and predict risk of future clinical changes. Brain MRI is now recommended at least annually for patients with relapsing MS to more accurately measure disease activity and inform therapeutic decision-making – and more often as needed to address specific clinical questions.1,159 The 2018 Revised Guidelines of the Consortium of MS Centers MRI Protocol for the Diagnosis and Follow-up of MS provides detailed recommendations for the use of MRI in CIS, diagnosis, and ongoing MS management.160

*Comparison across clinical trials is unreliable due to differences in patient populations, diagnostic definitions, primary and secondary endpoints, and outcome metrics.*

After the pivotal trials, several investigations have demonstrated an impact of treatment on the evolution of persistent T1 hypointensities (known as “black holes”) – which are associated with disability as measured by EDSS and considered to be indicative of tissue damage – and on changes in brain volume:

- In a placebo-controlled trial with monthly cerebral MRI, glatiramer acetate was shown to limit the evolution of newly formed lesions into chronic black holes.  
- In a phase III trial comparing BG-12 with placebo, which also included glatiramer acetate as an active reference arm, BG-12 and glatiramer acetate significantly reduced the numbers of new T1 hypointense lesions as compared with placebo.  
- Data analysis from phase III clinical trials and subsequent studies demonstrate a variable effect on brain atrophy.  

Table 4 summarizes the impact of disease-modifying therapies on brain volume loss (BVL) in relapsing-remitting patients in phase III clinical trials – with the following caveats: comparisons across studies cannot be made due to differences in assessment measures and study design; and current methods of MRI brain atrophy quantification provide sufficient precision for cohort studies but are not adequate for assessing changes in individual patients over months or a few years.

Of note, in a two-year, placebo-controlled trial, brain atrophy was greater in year one and less in year two in natalizumab-treated patients, leading some researchers to suggest that the brain atrophy seen in year one may have been “pseudoatrophy” – a reduction in sub-clinical inflammation in response to treatment. However, De Stefano and Arnold assert that a complete understanding of pseudoatrophy requires further study to clarify the possible underlying pathology.
Table 4: The effect of DMTs on BVL in RRMS patients in phase III trials.

Head-to-head comparison data in relapsing MS

In addition to the active comparator registration trial data reported in Table 2, the following comparison trials have been reported:

- **IFNB-1a 44mcg tiw vs. IFNB1a weekly (EVIDENCE):** A prospective, 24-week, randomized, controlled, multi-center trial of 677 RRMS patients demonstrated superior efficacy in favor of IFNB-1a tiw in the number of relapse-free patients (p=0.0005) and active MRI lesions (p<0.001).183
- **IFNB-1a IM weekly + GA 20 mg SC daily vs. IFNB-1a IM weekly or GA 20 mg SC daily (CombiRx):** A double-blind, randomized, controlled study that followed patients for a minimum of three years found: the combination to be significantly better than IFN alone in reducing the risk of relapse and superior to either agent alone in reducing new lesion activity and accumulation of total lesion volume; GA to be significantly better than IFN in reducing the risk of relapse; the combination to be no better than either agent alone in reducing progression.184
- **IFNB-1b vs. GA (BECOME):** A prospective, randomized, single-blind (MRI rater), one-year study of 75 RRMS patients demonstrated no difference in MRI outcomes.185
- **IFNB-1b 250 mcg or 500 mcg vs. GA (BEYOND):** A prospective, randomized, multi-center study of 2244 RRMS patients over 2-3.5 years demonstrated no difference in relapse rate, EDSS progression and MRI outcomes.186
- **Oral BG12 (dimethyl fumarate) (240 mg bid and tid) vs. GA (reference comparator) (CONFIRM):** A prospective placebo-controlled phase III, randomized trial of 1417 RRMS patients with GA as a reference comparator demonstrated the superiority of all three agents relative to placebo on risk of relapse (BG12 bid p=0.002; BG12 tid p<0.001; GA p=0.01); no significant reduction in disability progression for any of the agents; all agents superior to placebo on MRI outcomes p<0.001.148
- **IFNB-1b vs. IFNB-1a weekly (INCOMIN):** A prospective, 2-year, randomized, multi-center trial of 188 RRMS patients demonstrated superior efficacy in favor of IFNB-1b on risk of relapse (p=0.003) and MRI outcomes (p<0.0003).186
• **IFNB-1a tiw vs. GA (REGARD):** A prospective, randomized, comparative, parallel-group, open-label study of 764 RRMS patients demonstrated no difference between groups in time to first relapse and no significant differences for MRI outcomes except IFNB-1a patients had significantly fewer enhancing lesions (p=0.0002).^{177}

• **Teriflunomide vs. IFNB-1a tiw (TENERE):** A prospective, randomized, controlled, phase III, multi-center rater-blinded trial of 324 RRMS patients demonstrated: no difference in the primary outcome of time to failure (first appearance of confirmed relapse or permanent treatment discontinuation for any cause); and no difference in ARR (secondary outcome) between teriflunomide 14 mg and IFNB-1a, but ARR was higher with teriflunomide 7mg vs. IFN-1a (p=0.03).^{187}

• **Fingolimod vs. INFB-1a weekly (TRANSFORMS):** A prospective, 12-month, double-blind, randomized trial of 1153 RRMS patients demonstrated superior efficacy in favor of fingolimod with respect to relapse rate (p<0.001) and MRI outcomes (p<0.001).^{151}

• **Ocrelizumab vs. IFNB-1a tiw (OPERA I and II)** demonstrated the superiority of ocrelizumab in annualized relapse rate and MRI outcomes, as well as disability progression (pooled analysis) (see Tables 2 and 3).^{156}

Additional studies comparing various agents provide important information for healthcare providers and patients who are making complex treatment decisions:

• A large international, observational, prospectively acquired cohort study looking at relapse and disability outcomes in 792 RRMS patients who had disease activity while on IFN beta or GA and switched to either natalizumab or fingolimod, demonstrated a post-switch difference in relapse hazard (p=0.002) in favor of natalizumab and a significant sustained disability regression (p<0.001) also in favor of natalizumab.^{188}

• In the MSBase cohort study, Lizak and colleagues used longitudinal data from 4295 patients to evaluate time from baseline to EDSS epochs 3-6, 4-6 and 6-6.5. They found that disease progression in patients with moderately advanced and advanced MS occurs irrespective of prior disease activity and that lower relapse rates and greater time on higher efficacy disease-modifying agents (natalizumab, fingolimod, alemtuzumab, dimethyl fumarate, rituximab, mitoxantrone, cladribine) is associated with a decreased risk of further disability progression.^{189}

• A retrospective cohort study of 84 RRMS patients treated with natalizumab or INFB-1a 44 mcg tiw for at least 12 consecutive months demonstrated that both agents reduced ARR, but the effect was stronger in the natalizumab-treated group (p=0.0125). EDSS reduction favored natalizumab (p=0.0018). MRI outcomes were decreased with both agents. In the second year, ARR and EDSS progression were similar to year one; however, Gd-enhancing lesions decreased more significantly with natalizumab (p=0.008).^{190}

• Nixon and colleagues used a statistical modeling approach to account for differences in baseline characteristics and predict indirect relative risk of achieving NEDA (No Evidence of Disease Activity) status for fingolimod vs. dimethyl fumarate or teriflunomide in an average patient from their respective phase III trials. Results estimated that the relative risk of achieving NEDA status was greater with fingolimod than with the other therapies vs. placebo in each respective trial population.^{191}

**Evidence Demonstrating the Impact of Treatment on Progressive MS**

Many agents have been investigated for use in secondary progressive or primary progressive MS.^{192,193} Sub-group analyses from some of these clinical trials indicated benefits in patients of younger age with more recent progression, recent relapse and/or MRI activity.^{193} Only mitoxantrone, which is seldom used in the United States because of its high risk profile, has an FDA indication for secondary progressive MS.^{74} Only ocrelizumab has FDA approval for primary progressive MS.^{76} The remaining medications are approved for relapsing forms of MS, which include progressive MS in those patients who experience relapses.
Impact on long-term clinical outcomes

In addition to being expensive and difficult, it is unethical in the current treatment era to carry out long-term randomized controlled studies to assess the value of disease-modifying treatment compared to placebo on the course of MS. Hence, alternate methods for studying natural history in the treatment era need to be employed. Following an observational cohort of people over an extended period has limitations, including non-randomized design, difficulty accounting for drop-outs and, in some studies, retrospective assessments conducted on individuals seen at divergent time periods. However, important data have emerged demonstrating that early and ongoing treatment has a significant impact on long-term clinical outcomes:

- In a cohort observational study of 3,060 patients, disease-modifying therapies delayed long-term disability, as measured by the EDSS, in patients treated either early or, to a lesser extent, in the later phase of the disease compared to untreated patients.82
- In a longitudinal prospective study of newly-diagnosed MS patients at Karolinska Hospital between 2001-2005, early treatment was correlated with longer time from diagnosis to EDSS $\geq 4$.194
- The 10-year follow-up of the early intervention trial with interferon beta-1a (intramuscular) found a delayed conversion to clinically definite MS and reduced relapse rates in the early treated group compared to the delayed treatment group, but no difference in disability outcomes, most likely because both groups received treatment relatively early in the disease course.195
- In a nine-year follow-up of the pivotal phase III teriflunomide trial (TEMSO), a positive effect on disease activity persisted in the original treatment group as well as in the placebo patients who switched to active treatment in the open-label extension.196
- A long-term follow-up (greater than seven years) of a phase II fingolimod study demonstrated a persistent positive effect on relapse and MRI activity.197
- Approximately 90 percent of untreated RRMS patients will have SPMS after 15-26 years.198,199 Evidence from several studies now indicates that disease-modifying therapies have an impact on the conversion from relapsing to progressive MS:
  - In a study comparing the time interval from disease onset to secondary progression in relapsing-remitting patients treated with disease-modifying therapy and patients receiving no treatment, a significantly longer time to secondary progression was seen in the treated group.200
  - A study comparing treated and untreated patients over a 10-year period prior to the endpoint of conversion to secondary progressive MS found that treatment with a disease-modifying therapy significantly reduced the risk of disease progression in patients considered high- or low-risk at disease onset.201
  - In a study comparing patients treated with interferon beta for up to seven years with untreated patients, the treated group had a significant reduction in the incidence of secondary progression as well as in the incidence of EDSS progression.202
  - In a single center prospective observational study of 517 actively treated relapsing MS and CIS patients at a median time point of 16.8 years after disease onset, only 10.7 percent reached an EDSS $\geq 6.0$, and 18.1 percent evolved to secondary progressive MS.203
- The impact of early treatment on other clinical outcomes is also important. Extension study data from the early treatment trial with interferon beta-1b suggest that early treatment helps to preserve cognitive function compared to delayed treatment,204,205 with evidence suggesting that long-term (physical and cognitive) outcomes may be largely determined early in the disease course.115 Another study demonstrated decreased mortality in patients treated early in the course of their disease compared with those treated later,15 a finding that needs to be confirmed with the newer agents in long-term studies.
- Most of the extension studies from the pivotal trials indicated a positive impact on time to a second attack or new lesions, relapse rates and disease progression,115,137,175,204 although much of the impact has been thought to take place early in the disease course.115 In a more recent study, using data extracted from the global MSBase Registry, Jokubaitis and colleagues112 examined median EDSS score changes in 2,466 relapse-onset patients initially treated with either interferon-beta or glatiramer...
acetate. The patients (including those who stayed on their initial treatment, those who switched to other therapies and those who stopped treatment altogether) were treated an average of 83 percent of the follow-up period. The authors also found that annualized relapse rate was the strongest predictor of increases in median EDSS scores, with on-therapy relapses being more predictive than off-therapy relapses – and concluded that persistent relapse activity on a first-line therapy is prognostic of increasing disability.

**Impact on NEDA (no evidence of disease activity)**

NEDA is a term used to describe disease stability, including no new relapses, no disability progression and no new or enlarging MRI lesions.\(^{206,207}\) In addition, some researchers have proposed adding no additional brain volume loss to this definition (NEDA-4).\(^{208,209}\) Post-hoc analysis of several MS treatment trials has suggested that the goal of NEDA may be achievable for some individuals.\(^{206,207,210}\) The evidence to date suggests that NEDA is difficult to sustain over the long term even with treatment. On the basis of their seven-year longitudinal study, Rotstein and colleagues conclude that NEDA status at two years may be a good predictor of long-term disease stability and may be useful as a treatment outcome in investigations of new treatments for MS.\(^{207}\)

However, in a prospective single center observational study of 517 actively treated relapsing MS patients, NEDA at two years was not associated with better long term measures of disability by EDSS.\(^{203}\) In the 16- and 21-year follow-up from the pivotal trial of interferon beta-1b study patients, NEDA based on clinical features predicted long-term disability outcome; however adding MRI changes to the NEDA criteria did not increase predictive validity.\(^{211}\)

Although NEDA is a compelling concept and shared goal among people with MS and their healthcare providers, no consensus has yet emerged for the role of NEDA in making clinical decisions.

**Impact on quality of life**

Clinical and MRI outcomes do not fully capture the impact of MS disease-modifying therapies for people with MS. Unfortunately, efforts to assess the impact of treatment on quality of life have been limited. In one study of newly-diagnosed patients beginning treatment with an interferon medication, quality of life scores on the MSQoL-54 showed overall improvement at 12 months.\(^{212}\)

Not being on a disease-modifying therapy was one of the factors identified as contributing to a decrease in health-related quality of life in the NARCOMS database, although quality of life generally remained fairly stable for most people over the five years of the study.\(^{213}\) Health-related quality of life scores on physical and mental components of the Short Form (36) Health Survey (SF-36 – a patient-reported survey of health outcomes) improved in the pivotal trials of natalizumab.\(^{214}\) In the pivotal trial of dimethyl fumarate, patients on treatment evidenced a significant improvement in SF-36 physical component summary scores compared with placebo-treated patients whose scores worsened, and similar benefits were seen in other measures of functioning and general well-being as early as week 24.\(^{215}\)

Early treatment to reduce loss of mobility has been shown to help preserve people’s ability to carry out instrumental activities of daily living,\(^{216}\) and the ability to work was found to improve after one year of treatment with natalizumab.\(^{217}\)

In a review of existing data on the relationship between inflammation, patterns of CNS lesions and the effects of immunotherapeutics on MS fatigue, the disease-modifying therapies were observed to “effectively and sustainably stabilize and ameliorate fatigue in parallel to their dampening effects on the neuroinflammatory process.”\(^{218}\)

**Benefits gained through early treatment may never be equaled in those whose treatment is delayed**
Data suggest that benefits gained through early treatment, including delay of a second clinical event or MRI activity in CIS patients, reduced relapse rates and disability, may not be equaled in those who start treatment later in the disease course, suggesting that people who start treatment later may not “catch up” with those who start treatment immediately.

As stated earlier however, the 10-year follow-up to the early intervention trial with interferon beta-1a (intramuscular) found no difference in disability outcomes between the early- and delayed-treatment groups, indicating that the delayed treatment group did appear to experience a “catch up” in this particular outcome. It remains to be determined the extent to which the older medications – and the newer medications for which we have limited long-term data – impact longer-term disability outcomes for people with MS. Similarly, 11-year follow-up data on the CIS cohort treated with interferon beta-1b or placebo for up to two years prior to open label active therapy demonstrated no significant difference in EDSS outcome between groups.

**Evidence Supporting the Need for Treatment to be Ongoing**

Once a disease-modifying treatment is initiated, evidence suggests that treatment needs to be ongoing for benefits to persist. Cessation of treatment has been shown to negatively impact clinical and MRI outcomes.

- Non-adherence and gaps in treatment are associated with an increased rate of relapses and progression of disability.
- In a review of studies looking at treatment discontinuation, Tobin and Weinshenker concluded that discontinuation of treatment early in MS could lead to re-emergence of disease activity. The impact of treatment discontinuation in patients over the age of 60 with long-term progressive disease is less clear.
- In a review of the adherence results, relapse rate and progression were greater in those who stopped injectable disease-modifying treatment, and several reviewed trials showed an increase in emergency department utilization by patients who had stopped treatment.
- In one study, relapses and MRI activity returned to baseline following cessation of interferon therapy, although there was a several month refractory period before activity resumed. In another study, active patients treated with interferon beta promptly returned to pre-treatment levels of disease activity following discontinuation of treatment, leading the authors to recommend that treatment not be stopped in patients who are responding to treatment. A similar return to baseline disease activity in interferon-treated patients was observed in secondary progressive MS, with an increase in EDSS scores and MRI activity in the year after discontinuation of treatment.
- Relapse rates returned to baseline following interruption of natalizumab treatment in three large studies, and in a partially placebo-controlled exploratory study of disease activity during an interruption of natalizumab therapy, patients whose treatment was interrupted had an increased risk of disease and MRI activity compared with those on continuous treatment. In a retrospective study of patients refractory to interferon or glatiramer who had been switched to natalizumab and then stopped it, some patients had significant relapses – indicating that simple withdrawal of this medication without early implementation of an alternative treatment strategy may risk return of disease activity or rebound, typically within the first six months. In a study of 32 patients with MS who stopped natalizumab treatment, rebound was identified with an increase in relapses and high MRI activity compared to baseline.
- Cessation of fingolimod after a period of stability was followed by clinical relapse and multiple enhancing lesions on MRI in two patients, and both patients had a significant worsening in EDSS scores associated with their clinical activity. In another report of six cases of fingolimod discontinuation, five patients returned to pre-treatment disease activity within three months, and one patient had both clinical and MRI rebound activity. A recent review reported five individuals experiencing increased disease activity within 4-16 weeks following discontinuation of fingolimod therapy (10.9 percent of 46 patients discontinuing the drug during the two-year observation period) and identified 11 other reported cases of rebound disease activity.
These studies and case reports illustrate the need for ongoing disease-modifying treatment in MS. Regardless of the reason for the discontinuation of treatment – a decision by the treating clinician, patient non-adherence, cost or insurance coverage issues – these findings indicate that discontinuation or interruption of treatment will provoke a return of disease activity in many people.

**Situations in which discontinuation of treatment might be considered**

While there is ample evidence to support the benefits of ongoing treatment for the majority of people with MS, there may be some situations in which clinicians and their patients might consider stopping treatment. In a 2015 review of relevant studies, Tobin and Weinschenker conclude that although freedom from subsequent relapse is impossible to guarantee, treatment cessation may be considered in patients who:

- Are over 60 years of age
- Have experienced a progressive disease course for five years or longer
- Have no accumulating T2 lesions or gadolinium enhancing lesions on MRI of the brain or spinal cord after a period of observation over several years

Earlier discontinuation, particularly in patients with active disease, may lead to increased disease activity. Clinical and MRI monitoring for recurrent disease activity is clearly warranted in those patients.

**Use of Disease-Modifying Therapies in Pediatric MS**

Studies have estimated the incidence of pediatric MS to be between 0.18 and 0.51/100,000 children per year. Three to 10 percent of adult patients retrospectively report a possible first attack prior to age 18. More than 97 percent of children and adolescents experience a relapsing-remitting disease course, with annualized relapse rates 2-3 times that of adults with MS during the first three years of disease. In addition to motor and other physical symptoms that occur during relapse (and often resolve with relapse therapy), 30-40 percent of children with MS demonstrate cognitive impairment early in the disease course.

The interferon beta medications and glatiramer acetate have traditionally served as the initial treatment options for children with MS. The recently completed PARADIGMS trial, a double-dummy randomized trial comparing fingolimod to interferon beta-1a by subcutaneous injection demonstrated a clear superiority of fingolimod over interferon (82 percent reduction in relapse rate). Superiority of fingolimod was also demonstrated by MRI endpoints. The FDA has now approved fingolimod for pediatric MS, the first FDA approval for any MS therapy in this age group. While data regarding how the PARADIGMS results will alter clinical practice have yet to be accrued, the option of oral therapy will appeal to many children. Safety considerations, however, must be carefully considered. Structured screening protocols, such as ensuring up to date vaccination status (notably confirmation of vaccination against varicella zoster), ophthalmological and dermatological evaluations, and monitoring for first-dose effect bradycardia are critical. Pediatric centers may need to partner with adult MS centers to ensure consistent care programs for fingolimod use.

As in adults, however, evidence of ongoing relapses, MRI activity, and increasing disability (which is less common in pediatric MS patients) indicate the need to escalate to higher potency therapies. Considerations include switching from interferon or glatiramer acetate to oral or infused medications. In one study involving 258 children over a mean observation period of 3.9 years, a little more than half were successfully managed on the first medication they were given, while 25.2 percent were switched once, 11.2 percent were switched twice, and 7.8 percent required three changes in medication. While some were switched from one injectable medication to another, others required more aggressive treatment in order to control their disease. Several retrospective analyses regarding safety and tolerability of natalizumab support the use of natalizumab in pediatric MS patients with active or aggressive disease. Case report and case series data have advocated use of rituximab for patients...
requiring escalation of therapy, while future study of ocrelizumab in pediatric MS patients is awaited.

The importance of high quality data regarding therapeutic safety and efficacy has been emphasized and pediatric clinical trials of all new agents are mandated by the U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA). The PARADIGMS trial not only informed on the impact of fingolimod vs. interferon beta-1a on clinical and MRI disease activity in pediatric MS patients, it also provided new insight into the challenges of pediatric MS clinical trials. Enrollment took longer than anticipated, a multinational site study was required owing to the rarity of pediatric MS, and the burden of rigorous clinical trial monitoring and visits challenged patients, parents and providers. Nonetheless, it is imperative to determine how best to ensure that all trials produce informative data on therapeutic safety and efficacy, and the International Pediatric Multiple Sclerosis Study Group is preparing a working group manuscript that addresses these key considerations.

It is noteworthy that access to certain medications for pediatric MS patients in some world regions may be limited by regulation. It is hoped that clinical trial data will enhance regulatory approval and access.

**Treatment Considerations in Women and Men in Their Reproductive Years**

None of the FDA-approved disease-modifying therapies are approved for use during pregnancy or breastfeeding (see Table 1). Several observational studies, including pregnancy registries, have been done to identify potential risks of the disease-modifying therapies for fetal development and breastfeeding.

- **Glatiramer acetate** does not cross the placenta and is likely safe for use during breastfeeding. Confirming earlier findings in small studies, a prospective cohort study of 246 pregnancies (from the German Multiple Sclerosis and Pregnancy Registry), in which 151 women were exposed to glatiramer acetate (pregnancy category B) and 95 were taking no disease-modifying therapy, found no impact on several major pregnancy outcomes (risk for congenital anomaly, lower birth weight, pre-term birth or spontaneous abortion).

- **Beta-interferon** crosses the placenta in minimal quantities; it is unknown whether it is excreted in breast milk. Using the same German Multiple Sclerosis and Pregnancy Registry database, a prospective study of 445 pregnancies, in which 251 women were exposed to interferon-beta and 194 were taking no disease-modifying therapy, found no differences in mean birth weight and length, pre-term birth, spontaneous abortion or congenital anomalies.

- **Teriflunomide** carries a boxed warning about the risk of teratogenicity (see Table 1). This medication crosses the placenta; it is unknown whether it is excreted in human milk. A study of 105 pregnancy exposures (83 female and 22 male) to teriflunomide for varying lengths of time found no increase in spontaneous abortion rate or fetal abnormalities. A rapid elimination program using oral cholestyramine over several days is recommended for women to lower teriflunomide levels to less than 0.02 µg/ml. Men taking teriflunomide should stop the medication before trying to conceive and discuss rapid elimination with their healthcare providers. The 2018 AAN Practice Guideline includes a Level B recommendation that clinicians should counsel men with MS regarding the implications of their treatment decisions for their reproductive plans before initiating treatment with a chemotherapeutic agent such as teriflunomide or cyclophosphamide. Refer to AAN.com/guidelines.

- **Fingolimod** crosses the placenta and is excreted in breast milk. A pregnancy registry is ongoing and patients are advised to use effective contraception and wait at least two months before attempting conception.

- **It is unknown whether dimethyl fumarate crosses the placenta or enters breast milk.** Animal studies of teratogenicity have shown conflicting results. Because of its short half-life (approximately one hour), no washout may be necessary.

- **Natalizumab** crosses the placenta and is excreted in breast milk. Compared with historical controls, no significant difference has been found in the rate of fetal malformations in MS and Crohn’s clinical trial programs or the Tysabri Pregnancy Exposure Registry.
• Mitoxantrone crosses the placenta in limited amounts and is excreted in breast milk.\textsuperscript{74} Patients should be instructed not to become pregnant while taking mitoxantrone and for at least six months after discontinuation.\textsuperscript{255}

• Alemtuzumab crosses the placenta; it is not known whether it is excreted in breast milk. Because alemtuzumab has the potential for serious adverse reactions in infants, women should be advised not to breastfeed while on this medication.\textsuperscript{70} There are no adequate and well-controlled studies in pregnant women.\textsuperscript{70}

• Ocrelizumab is a humanized monoclonal antibody of an immunoglobulin G1 subtype and immunoglobulins are known to cross the placental barrier. Following administration to pregnant monkeys, at doses 2–10 times the approved human dose by weight, increased perinatal mortality, depletion of B-cell populations, renal, bone marrow and testicular toxicity were observed in the offspring. Women of childbearing age should use contraception while receiving ocrelizumab and for six months after the last dose. There are no data on the presence of ocrelizumab in human milk; it is excreted in the milk of ocrelizumab-treated monkeys. Human IgG is excreted in human milk, and the potential for absorption of ocrelizumab to result in B-cell depletion in infants is unknown.\textsuperscript{76}

The current standard of care is to avoid the use of disease-modifying therapies during pregnancy and breastfeeding.\textsuperscript{256–258,264–267} Based on exponential decay, the commonly accepted timeframe for drug discontinuation before conception is five maximal half-lives – approximately two to six weeks,\textsuperscript{266} with two months recommended for fingolimod and at least three months for natalizumab.\textsuperscript{264} However, there is increasing evidence that glatiramer acetate and interferon-beta may be continued safely during conception and pregnancy in a woman with very active disease.\textsuperscript{264,265,268–270} The risks and benefits of continuing therapy during pregnancy require careful discussion, taking into account the level of disease activity, personal preferences and the patient’s and doctor’s risk tolerance. Similarly, a discussion about the risks and benefits of postponing resumption of treatment in order to breastfeed is important, particularly for women who had active disease in the year prior to conception.\textsuperscript{257} In a recent study, natalizumab started within eight days of delivery successfully prevented post-partum relapses in five of six women with very active disease.\textsuperscript{271}

**Rationale for Access to the Full Range of Treatment Options**

At present, 15 medications are FDA-approved to treat MS (See Table 1), with ten different mechanisms of action that are thought to address distinct components of the immune-mediated disease process. These medications also differ in their route and frequency of administration as well as their side effects and risk profiles. *None of these medications are curative and the efficacy of any given medication varies considerably from one individual to another and for any given individual at different points in time.* In addition, people with MS differ in their tolerance for different routes of administration and side effects, and clinicians and patients vary in their tolerance for risk, with risk tolerance likely undergoing shifts as the disease progresses. Access to the full range of options is essential to optimal management, for the following nine reasons.

1. **Non-responders need access to other options**

   The goal of treatment is to control disease activity and prevent irreversible damage as quickly and effectively as possible. When a person’s medication does not provide sufficient suppression of disease activity or provides initial benefit and then ceases to do so – as determined by the individual and his or her clinician in light of continued clinical and/or MRI disease activity – the reasons for lack of efficacy need to be explored\textsuperscript{272} and alternative options need to be considered.\textsuperscript{80} It is known, for example, that disease activity which occurs in spite of treatment with IFN beta or GA is associated with unfavorable long-term outcomes.\textsuperscript{112,273,274} Furthermore, MRI activity as well as relapses are key indicators of progression\textsuperscript{275,276} and the presence of Gd-enhancing lesions has been shown to correlate with worsening disability after 15 years.\textsuperscript{273}

2. **The effort to achieve NEDA requires access to the full range of treatment options**
To achieve NEDA or the lowest possible level of subclinical disease activity, the authors of “Brain Health: Time Matters in Multiple Sclerosis” (endorsed by the MS Coalition) recommend swift action in the face of disease activity, including consideration of switching to another disease-modifying therapy with a different mechanism of action.277

3. Treatment with interferon beta and natalizumab is associated with the development of neutralizing antibodies (NAbs)

Although comparisons are challenged by lack of standardization in assays and lack of consensus concerning the relevant threshold of NAb concentration,278 the phase III trials of the interferon beta medications,144–146 as well as subsequent direct comparison studies,279,280 have demonstrated that NAbs are a common occurrence with these medications and that there is significant variability between the medications in terms of their occurrence. Furthermore, the studies suggest that the presence of NAbs reduces the clinical efficacy of interferon beta – although the impact may not be clear for some time.278 Determining the impact of NAbs for any given individual is further complicated by the fact that NAb-positive patients may revert to NAb-negative status or fluctuate between positive and negative NAb status.279 However, the fact remains that a person who has persistent disease activity on interferons, regardless of whether or not this is due to NAbs, requires access to non-interferon treatment options.281,282

In two phase III clinical trials of natalizumab,155,283 the incidence of persistent antibody positivity associated with the drug was 6 percent. Compared with antibody-negative patients, those with persistent antibody positivity had a significantly higher relapse rate and more activity on MRI in both studies, as well as significantly greater disease progression in one of the studies.284 Persistent antibody positivity was also associated in both studies with a higher incidence of infusion-related adverse events, including hypersensitivity reactions.284

Of the 58 percent of patients in a prospective observational study of 73 consecutive patients285 who developed NAbs, the vast majority reverted to antibody-negative status on follow-up. In this study, the presence of NAbs was inversely correlated with serum natalizumab concentration, and high antibody titers and low serum natalizumab concentrations were associated with an increase in relapses and Gd-enhancing lesions on MRI.

4. Individuals at high-risk for PML need access to other options

People who are or become JC antibody-positive need access to treatments that do not put them at risk for PML.

- The boxed warning for Tysabri (natalizumab) states that the risk factors for the development of PML include duration of therapy, prior use of immunosuppressants and the presence of anti-JCV antibodies – and that these factors should be taken into account when initiating and continuing treatment with this medication.75
- The prescribing information for Gilenya (fingolimod) states that the medication should be withheld at the first sign or symptom suggestive of PML.67 It is not known whether individuals with anti-JCV antibodies taking fingolimod are at higher risk of PML given the limited number of PML cases to date with this agent.
- The prescribing information for Tecfidera (dimethyl fumarate) states that the medication should be withheld at the first sign or symptom suggestive of PML.66 It is not known whether individuals with anti-JCV antibodies taking dimethyl fumarate are at higher risk of PML given the limited number of PML cases to date with this agent.
- The prescribing information for Ocrevus (ocrelizumab) states that PML is possible with this medication.76

A PML risk stratification for disease-modifying therapies is summarized in Table 4.286
TABLE 4: A PML risk stratification table for disease modifying therapies.*

5. Individuals with contraindications need access to suitable options

For a variety of reasons (cited as contraindications in medication labeling), 5,4,5,5,7,60–63,66–68,70,74–76 individuals may not be suitable candidates for one or another of the available disease-modifying therapies:

- Hypersensitivity to glatiramer acetate or mannitol, precluding the use of glatiramer acetate
- Hypersensitivity to natural or recombinant interferon beta, albumin or other component of the formulation, precluding the use of interferon medications
- Hypersensitivity to dimethyl fumarate or to any of the excipients, precluding the use of dimethyl fumarate
- Cardiac or ocular conditions, or treatment with Class 1a or Class III anti-arrhythmic drugs, precluding the use of fingolimod
- Hypersensitivity to fingolimod or its excipients, precluding the use of fingolimod
- Current use of leflunomide, precluding the use of teriflunomide
- Infection with HIV, precluding the use of alemtuzumab
- Hypersensitivity reaction to natalizumab, precluding the use of natalizumab
• Current or past diagnosis of progressive multifocal leukoencephalopathy (PML), precluding the use of natalizumab
• Severe hepatic impairment, precluding the use of fingolimod, interferons, natalizumab and teriflunomide
• Positive tuberculosis screening requiring standard TB treatment prior to teriflunomide dosing
• Active hepatitis B infection, precluding the use of ocrelizumab
• History of life-threatening infusion reaction to ocrelizumab, precluding its use

In addition to these contraindications, post-marketing data (Avonex; Rebif; Betaseron; Extavia) have led many clinicians to avoid the use of interferon beta medications in individuals who are depressed or have a history of significant depression. Although several studies have found no increased frequency of depression in patients taking interferon beta medications compared with those not taking these medications, interferon beta medications may exacerbate or precipitate depression in some patients as warned in the FDA prescribing information.

Other co-morbid conditions may impact use of a particular disease modifying therapeutic agent in individual circumstances compromising safety, efficacy or tolerability and necessitating access to an alternative option.

6. Because severity of disease varies at onset – with some adults experiencing early aggressive disease – patients and their treating clinicians need access to all available options

Although MS remains a highly unpredictable disease, certain clinical and MRI outcomes seem to be associated with a higher risk of disease progression:

• Scalfari and colleagues found that time to Expanded Disability Status Scale (EDSS) 3 highly and independently predicted time to EDSS 6, 8 and 10. The same group found that higher early relapse frequencies and shorter first inter-attack intervals increased the probability of – and hastened conversion to – secondary progression, and that although long-term outcomes were highly variable, some individuals who experienced frequent relapses and/or accumulated a large number of focal lesions on T2 MRI within the first five years were at greater risk of disability.

• Fisniku and colleagues found lesion volume and its change at earlier time points to be correlated with disability after 20 years. In their study, lesion volume increased for at least 20 years in relapse-onset MS and the rate of lesion growth was three times higher in those who developed secondary progression than in those who remained relapsing-remitting.

• A prospective study in British Columbia that utilized three possible criteria for aggressive MS – confirmed Expanded Disability Status Scale (EDSS) ≥6 within five years of MS onset; confirmed EDSS ≥6 by age 40; and secondary progressive MS within three years of a relapsing-onset course – identified aggressive MS in 4-14 percent of people depending on the definition used. Although the majority were males and those with PPMS, there were also a significant number of female patients and patients with RRMS.

• In a retrospective database study of aggressive onset MS, defined as two or more relapses in the year after onset and two or more Gd-enhancing lesions on MRI or one relapse if resulting in an EDSS of 3 along with two or more Gd-enhancing lesions, those patients who received or were switched to one of the following therapies – natalizumab, rituximab, alemtuzumab or cyclophosphamide – maintained a NEDA status during the 54-month mean duration of follow-up.

• Utilizing a different definition of aggressive MS that requires one or more of the following features, Rush and colleagues recommend more aggressive treatment agents to manage this challenging group of patients.

- EDSS of 4 within five years of onset;
- Multiple (>2) relapses with incomplete resolution within the past year;
- More than two MRI studies showing new or enlarging T2 lesions or Gd-enhancing lesions despite treatment;
- No response to therapy with one or more DMTs for up to one year.

Given these findings, patients with highly inflammatory and potentially aggressive disease may determine with their treating clinician that the benefit-to-risk ratio warrants starting or switching to a therapy with a higher potency and risk profile.\textsuperscript{294}

In fact, the 2018 AAN Guideline\textsuperscript{78} states as a Level B recommendation that “Clinicians should prescribe alemtuzumab, fingolimod, or natalizumab for people with highly active MS.”

Data also support the use of mitoxantrone.\textsuperscript{295–298} However, as noted previously, mitoxantrone is seldom prescribed because of its high risk profile. The 2018 AAN Guideline states as a level B recommendation that “Because of the high frequency of severe AEs, clinicians should not prescribe mitoxantrone to people with MS unless the potential therapeutic benefits greatly outweigh the risks.” Refer to AAN.com/guidelines.\textsuperscript{78}

7. Some children experience very active disease from onset

As previously mentioned, some children may experience very active disease that does not respond to the medications generally considered to be first-line treatment options for pediatric-onset MS.

8. African-Americans and Hispanics appear to have more active disease

Several studies have now pointed to a more active disease course in African-Americans and Hispanics with MS.

- In a multicenter study of retinal damage and vision loss, African-Americans with MS were found to have accelerated damage compared to Caucasian MS patients, suggesting a more aggressive inflammatory disease course.\textsuperscript{21}
- In a different cohort, primary progressive MS was more common in African-American patients, as was cerebellar dysfunction and a more rapid progression of disability.\textsuperscript{22}
- Compared to Caucasians, African-American patients have also been found to have a greater likelihood of developing opticospinal MS and transverse myelitis and have a more aggressive course.\textsuperscript{23}
- More than one study has shown increased lesion volumes in African-Americans,\textsuperscript{24,25} with one also showing more tissue damage.\textsuperscript{24}
- Given that there are also preliminary indications that African-Americans may not respond as well to some of the available disease-modifying therapies,\textsuperscript{299,300} it is essential for African-American patients and their clinicians to have access to the full range of treatment options in the event that one or another does not provide sufficient benefit.
- Hispanics as well as African Americans could be at greater risk of greater disease burden early in the disease course, while also facing greater barriers to care.\textsuperscript{26–29}
- Hispanics, along with African Americans and Asians, are more likely to develop opticospinal MS than Caucasians, often leading to greater ambulatory disability.\textsuperscript{30}

9. People who for one reason or another are not adhering to a treatment regimen need access to other treatment options.

In a retrospective cohort study of people starting treatment with interferon beta or glatiramer acetate, only 3040 percent were adherent to treatment after two years.\textsuperscript{301} People who do not adhere to their treatment regimen are unlikely to receive the full benefit of the treatment.\textsuperscript{302,303} Factors associated with non-adherence include:
- Perceived lack of efficacy in relation to expectations\textsuperscript{303,304}
- Route of administration\textsuperscript{305,306}
- Perceived risks\textsuperscript{304,307,308}
- Tolerability issues with self-injectable medications, including flu-like symptoms and injection-site reactions\textsuperscript{309–312}
- Length of time on treatment\textsuperscript{308}
- Costs\textsuperscript{313}
- Psychosocial factors, including coping style,\textsuperscript{314} mood,\textsuperscript{315,316} and “forgetting”\textsuperscript{308,311,312}

Addressing adherence issues begins with identifying the non-adherent patient so that the cause(s) can be addressed. In some instances, this may require an alternative treatment option that is likely to enhance the person’s ability to adhere to the treatment plan.

**Under certain circumstances, other off-label agents may be needed to modify the disease course**

For all the same reasons that clinicians and their patients need access to the full range of approved disease-modifying therapies, they may also need to turn to non-approved options that have demonstrated efficacy in people with MS (see Appendix C for further information about these off-label options).
CONCLUSIONS REGARDING THE NEEDS OF PEOPLE WITH MS

Although there is still much that we do not fully understand about the pathophysiology of MS, the last 20 years have provided a significant number of treatment options that improve prognosis and quality of life for people with MS. Furthermore, the growing body of evidence highlights the importance of early and ongoing access to and treatment with disease-modifying therapies.

Treatment Considerations

- Initiation of treatment with an FDA-approved disease-modifying therapy is recommended:
  - As soon as possible following a diagnosis of relapsing or primary progressive multiple sclerosis, regardless of the person’s age.
  - For individuals with a first clinical event and MRI features consistent with MS, in whom other possible causes have been excluded.
  - For individuals with progressive MS who continue to demonstrate clinical relapses and/or demonstrate inflammatory activity.
- Clinicians should consider prescribing a high efficacy medication such as alemtuzumab, fingolimod, ocrelizumab or natalizumab for newly-diagnosed individuals with highly active MS.
- Clinicians should also consider prescribing a high efficacy medication for individuals who have breakthrough activity on another disease-modifying therapy, regardless of the number of previously used agents.
- Treatment with a given disease-modifying medication should be continued indefinitely unless any of the following occur (in which case an alternative disease-modifying therapy should be considered):
  - Sub-optimal treatment response as determined by the individual and his or her treating clinician
  - Intolerable side effects, including significant laboratory abnormalities
  - Inadequate adherence to the treatment regimen
  - Availability of a more appropriate treatment option
  - The healthcare provider and patient determine that the benefits no longer outweigh the risks
- Movement from one disease-modifying therapy to another should occur only for medically appropriate reasons as determined by the treating clinician and patient.
- When evidence of additional clinical or MRI activity while on consistent treatment suggests a sub-optimal response, an alternative regimen (e.g., different mechanism of action) should be considered to optimize therapeutic benefit.
- The factors affecting choice of therapy at any point in the disease course are complex and most appropriately analyzed and addressed through a shared decision-making process between the individual and his or her treating clinician. Neither an arbitrary restriction of choice nor a mandatory escalation therapy approach is supported by data.

Access Considerations

- Due to significant variability in the MS population, people with MS and their treating clinicians require access to the full range of treatment options for several reasons:
  - Different mechanisms of action allow for treatment change in the event of a sub-optimal response
  - Potential contraindications limit options for some individuals
  - Risk tolerance varies among people with MS and their treating clinicians
  - Route of delivery and side effects may affect adherence and quality of life
  - Individual differences related to tolerability and adherence may necessitate access to different medications within the same class
  - Pregnancy and breastfeeding limit the available options
- Individuals’ access to treatment should not be limited by their frequency of relapses, level of disability, or personal characteristics such as age, sex or ethnicity
- Absence of relapses while on treatment is a characteristic of treatment effectiveness and should not be considered a justification for discontinuation of treatment
• Treatment should not be withheld to allow for determination of coverage by payers as this puts the patient at risk for recurrent disease activity

REFERENCES

APPENDIX A: Multiple Sclerosis Disease Courses 2013 Revisions

In 2013, the International Advisory Committee on Clinical Trials of MS updated the disease course descriptions that were first published in 1996 (Lublin & Reingold, 1996), based on advances in the understanding of the disease process in MS and in MRI technology. The updated disease courses are clinically isolated syndrome (CIS), relapsing-remitting MS (RRMS), primary progressive MS (PPMS) and secondary progressive MS.

Clinically Isolated Syndrome (CIS) – a first episode of inflammatory demyelination in the central nervous system that could become MS if dissemination in time and space are established.

According to the 2017 revisions to the diagnostic criteria for MS, the diagnosis of MS in a patient with CIS (with evidence of > 2 lesions) can be made when establishing dissemination in time – when there is an additional clinical attack; or simultaneous presence of both enhancing and non-enhancing, symptomatic or asymptomatic MS- typical MRI lesions; or new T2 or enhancing MRI lesion compared to baseline scan (without regard to timing of baseline scan); or CSF-specific (i.e., not in serum) oligoclonal bands.

In a patient with CIS (with objective clinical evidence of 1 lesion), the diagnosis can be made if dissemination in space and dissemination in time are established. Dissemination in space would be established by an additional attack implicating a different CNS site or > 1 MS-typical symptomatic or asymptomatic T2 lesions in > 2 areas of the CNS. Dissemination in time would be established by when there is an additional clinical attack; or simultaneous presence of both enhancing and non-enhancing, symptomatic or asymptomatic MS- typical MRI lesions; or new T2 or enhancing MRI lesion compared to baseline scan (without regard to timing of baseline scan); or CSF-specific (i.e., not in serum) oligoclonal bands.

Continue onto the following pages for text and graphics describing the other disease courses.

---

**Relapsing-Remitting MS (RRMS)** – episodes of acute worsening of neurologic functioning (new symptoms or worsening of existing symptoms) with total or partial recovery and no apparent progression of disease. RRMS can be further characterized as:

**Active** – showing evidence of new relapses, new gadolinium-enhancing lesions and/or new or enlarging T2 lesions on MRI over a specified time **OR**

**Not active** – showing no evidence of disease activity

**AND**

**Worsening** – increased disability confirmed over a specified time following a relapse **OR**

**Stable** – no evidence of increasing disability over a specified time following a relapse
**Primary Progressive MS (PPMS)** – steadily worsening neurologic function (accumulation of disability) from the onset of symptoms without initial relapses of remission. PPMS can be further characterized as:

**Active** – showing evidence of new relapses, new gadolinium-enhancing lesions and/or new or enlarging T2 lesions on MRI over a specified time **OR**

**Not active** – showing no evidence of disease activity

**AND**

**With progression** – evidence of disease worsening on an objective measure of change, confirmed over a specified time, with or without relapses **OR**

**Without progression** – no evidence of disease worsening on an objective measure of change over a specified time
Secondary Progressive MS (SPMS) – following an initial relapsing-remitting course, the disease becomes more steadily progressive, with or without relapses. SPMS can be further characterized as:

**Active** – showing evidence of new relapses, new gadolinium-enhancing lesions and/or new enlarging T2 lesions on MRI over a specified time **OR**

**Not active** – showing no evidence of disease activity **AND**

**With progression** – evidence of disease worsening on an objective measure of change, confirmed over a specified time, with or without relapses **OR**

**Without progression** – no evidence of disease worsening on an objective measure of change over a specified time

APPENDIX C: Treatments Used Off-Label for Multiple Sclerosis

The U.S. Food and Drug Administration (FDA) has approved medications for the treatment of relapsing forms of MS, as well as one medication for secondary progressive MS (SPMS) and one for primary progressive MS (PPMS). However, response to these medications is variable and each has contraindications, side effects and risks that restrict their use for some people. In addition, barriers to access may exist for some people with one or another of the approved medications. Over the past few decades, several medications have been prescribed for the treatment of MS that have FDA approval for diagnoses other than MS. For each of these agents, there is some, but often limited clinical trial evidence of efficacy in MS. The available information is summarized here. Information about hematopoietic stem cell transplantation is also provided.

Azathioprine (Imuran®)

Azathioprine is an oral immunosuppressant drug that targets activation, proliferation, and differentiation of both T and B lymphocytes. Azathioprine is FDA-approved for use in combination with other medications to prevent organ rejection after kidney transplant and for the treatment of active rheumatoid arthritis.

It is used outside of FDA approval for conditions such as Crohn’s disease, ulcerative colitis, lupus, autoimmune hepatitis, neuromyelitis optica, myasthenia gravis and multiple sclerosis.

Azathioprine has been used in MS for over 30 years; however, the results of clinical trials with this agent have been mixed.2

- A meta-analysis of placebo-controlled, double-blind, randomized trials in MS3 concluded that azathioprine is probably effective in reducing relapses and may reduce the risk of progression.
- In a study comparing interferon beta-1a used alone vs. interferon beta-1a plus azathioprine or interferon beta-1a plus azathioprine and prednisone, no difference was found between the groups in annualized relapse rate, cumulative probability of sustained disability progression, change in percentage of brain volume loss or T2 lesion volume.4 Follow-up after 6 years of treatment yielded similar results.5
- Lus and colleagues6 evaluated the impact of azathioprine plus interferon beta-1a in three groups of relapsing-remitting patients: 1) a group with no prior treatment; 2) a group with inadequate response to prior treatment with azathioprine; and 3) a group with inadequate response to prior treatment with interferon beta-1a. The combined treatment reduced the mean number of relapses in all three groups and reduced the mean Delta EDSS score in groups 2 and 3. The combined treatment also resulted in significantly reduced MRI activity.
- A small two-year pilot study7 of azathioprine combined with interferon beta-1b in patients with secondary progressive MS whose disease had not been adequately controlled with interferon beta-1b alone reported a reduction in annual relapse rate of about 50 percent in year 2, a significant trend for an increase in EDSS, a decrease in lesion load on MRI at 12 and 24 months and a significant improvement in neuropsychological testing after 24 months. The investigators concluded that the combination treatment was safe and generally well tolerated; however, they recommended strict clinical and laboratory monitoring during treatment with this combination.
- In an open-label pilot trial8 to evaluate the addition of oral azathioprine to interferon beta-1b in patients who had break-through disease on interferon beta-1b alone, patients had a 65 percent reduction in the number of Gd-enhancing lesions compared to their baseline values. A total WBC count less than 4800/mm³ was the best predictor of MRI response.
- In a single-blind study9 comparing azathioprine with interferon beta over one year, the proportion of relapse-free patients was greater in the azathioprine group and the mean EDSS was also improved in this group.
Azathioprine is approved to treat MS in parts of Europe.

Side effects and risks include abdominal pain, severe nausea, vomiting, loss of appetite, mouth sores/ulcers, increased risk of infection, hair loss, change in hair color and texture, and risk of malignancies and blood abnormalities. Azathioprine can cause fetal abnormalities.

**Cladribine**

Cladribine, a purine nucleoside analogue prodrug, reduces lymphocyte subtypes, specifically CD4+ T cells, CD8+ T cells and B cells, as well as pro-inflammatory chemokine levels. A parenteral form of cladribine is approved as a treatment for hairy cell leukemia.

In MS, two early studies of cladribine injected subcutaneously (SC) yielded conflicting results in patients with progressive MS. An 18-month randomized controlled trial of SC cladribine in relapsing-remitting MS demonstrated significant benefits of cladribine vs. placebo in reducing both the frequency and severity of relapses, as well as improvement in MRI variables. However, concerns about the depletion of total lymphocyte count raised safety concerns.

The subsequent creation of an oral formulation of cladribine increased interest in cladribine for the treatment of MS:

- In a phase 3 clinical trial of oral cladribine that included 1,326 relapsing-remitting patients randomized to receive one of two doses of cladribine or placebo for 96 weeks, both treatment doses significantly reduced the rate of relapses, disease progression and MRI measures of disease activity.
- In a phase 3 trial of oral cladribine in 616 patients with a first demyelinating event randomized to receive one of two doses of cladribine or placebo, both doses of cladribine significantly delayed the diagnosis of MS compared with placebo.

The most common adverse event with cladribine is lymphocytopenia, which is sometimes severe. Infections and infestations can also occur, particularly herpes zoster. In the clinical trials, malignant neoplasms were identified in the cladribine treatment groups. Cladribine is a pregnancy category D.

The medication was approved in 2010 in Russia and Australia.

In a meta-analysis of phase III trials of licensed disease-modifying therapies for relapsing MS and a phase III trial of cladribine, no evidence was found of an increased cancer risk for cladribine. Based on these data, the EMA approved Mavenclad in 2018. Merck has also filed for an NDA to the FDA.

**Cyclophosphamide (Cytoxan®)**

Cyclophosphamide is an alkylating agent related to nitrogen mustard that binds to DNA and disrupts cell replication. In MS, the treatment serves as a general immune suppressant impacting cell-mediated and humoral immunity. It is given intravenously or orally.

Cyclophosphamide is FDA-approved for the treatment of various types of cancers. It is used off-label to treat autoimmune conditions such as Wegener’s granulomatosis, myasthenia gravis, lupus, rheumatoid arthritis and multiple sclerosis.

Placebo-controlled trials in progressive MS populations with different dosing regimens have found no benefit over placebo. However, several trials in people with active relapsing MS have demonstrated a reduction in relapses, fewer new areas of CNS inflammation and a variable effect on disease worsening, highlighting the usefulness of cyclophosphamide in younger, inflammatory and less progressed patients.
• Monthly intravenous cyclophosphamide led to improvement and neurologic stability within six months, sustained for at least 18 months after treatment onset, in patients with rapidly deteriorating relapsing-remitting MS. 

• In a combination trial of cyclophosphamide and interferon beta, with follow-up at 12 and 24 months, Reggio and colleagues found that the combination treatment halted disease progression in active, deteriorating MS patients who had received insufficient benefits from interferon beta alone.

• In a study of 10 patients with very active disease and severe frequent attacks who had not benefited from interferon beta alone, Patti and colleagues used pulsed cyclophosphamide to obtain a chronic lymphocytopenia, resulting in a marked and significant relapse reduction, improvement in disability and reduction of T2 burden of disease. Thirty-six months after discontinuation of cyclophosphamide, clinical and MRI benefits were maintained.

• In a randomized single-blind, parallel-group, multi-center trial, combination therapy using pulsed cyclophosphamide with methylprednisolone along with interferon beta-1a significantly decreased the number of Gd-enhancing lesions and slowed clinical activity in patients who had experienced active disease on interferon beta alone.

Side effects and risks include nausea, vomiting, hair thinning/loss, low white blood cell count, risk of infections, risk of cancers, infertility, and inflammation of the bladder with bleeding. Cyclophosphamide causes fetal abnormalities.

**Minocycline**

Minocycline is an oral tetracycline antibiotic that is FDA approved for the treatment of a number of different types of bacterial infection. It is used off-label as a treatment for rheumatoid arthritis. Minocycline has also been studied in conditions such as osteoporosis, schizophrenia, cystic fibrosis and multiple sclerosis.

• In patients with RRMS, interferon beta-1a plus minocycline was found to be no more effective than interferon beta-1a plus placebo in time to first relapse, annualized relapse rate, number of new or enlarging T2 lesions on MRI, or change in brain volume.

• In patients with RRMS, minocycline plus glatiramer acetate was found to be safe and well-tolerated, and reduced the number of T1 gadolinium-enhanced lesions, the total number of new and enlarging T2 lesions, and the total T2 burden of disease compared to glatiramer acetate plus placebo.

Side effects and risks include gastrointestinal problems, liver damage, mild to severe skin conditions, respiratory problems, kidney toxicity, muscle and joint pain, blood cell abnormalities and central nervous system disorders. Minocycline is a pregnancy category D medication, indicating potential for fetal abnormalities.

**Mycophenolate mofetil (Cellcept®)**

Mycophenolate mofetil is an immunosuppressant given by mouth twice daily that selectively inhibits an enzyme responsible for the de novo synthesis of the DNA nucleotide guanine within T-cells, B-cells and macrophages. It is FDA approved for preventing rejection in patients receiving organ transplants and is used off-label for lupus, certain types of skin diseases and immune system-related diseases, including multiple sclerosis.

• Mycophenolate mofetil has been studied in small, open-label trials as a monotherapy or in combination with interferon beta or glatiramer acetate and in two blinded, placebo-controlled pilot studies in combination with interferon beta-1a.
• Mycophenolate mofetil has also been compared with interferon beta-1a in a small randomized, blinded, parallel group pilot trial in patients with relapsing-remitting MS.37

The results of these studies suggest that mycophenolate mofetil may reduce the annual number of MS relapses, limit new areas of CNS damage and may slow disease worsening, however additional studies are needed to confirm these benefits.2

Side effects and risks include increased risk of infection (including opportunistic infections such as PML), nausea, diarrhea, stomach pain, weakness, dizziness, difficulty sleeping, increased risk of skin cancer and lymphoma, stomach ulcers and bleeding, elevation in liver enzymes and jaundice. Mycophenolate mofetil can cause fetal death or malformations.

Rituximab (Rituxan®)

Rituximab38 is a chimeric monoclonal antibody that targets CD20 on the surface of B-lymphocytes, which are known to cause inflammation and damage in MS.

Rituximab is FDA approved for the treatment of several conditions including non-Hodgkin’s lymphoma, chronic lymphocytic leukemia, rheumatoid arthritis and granulomatosis with polyangiitis, and microscopic polyangiitis. It has been used successfully off-label to treat neuromyelitis optica, multiple sclerosis, myasthenia gravis, autoimmune encephalitis, and autoimmune neuropathies and myopathies.39

Several clinical trials in MS have demonstrated that rituximab is effective in reducing clinical relapses and limiting new inflammation in the central nervous system.40

• In a phase 2, double-blind, 48-week trial in relapsing-remitting MS, a single course of rituximab reduced inflammatory brain lesions and clinical relapses for 48 weeks.41
• A randomized, double-blind, placebo-controlled study of rituximab in primary progressive MS came close to meeting its endpoint, suggesting that selective B-cell depletion may slow disease progression in younger patients with inflammatory lesions.42
• Rituximab was found to be more effective than fingolimod in reducing the risk of clinical relapses and contrast-enhancing lesions in stable relapsing-remitting MS patients who switch from natalizumab after becoming JC virus antibody positive.43
• In a retrospective uncontrolled observational multicenter study that included relapsing-remitting, secondary progressive and primary progressive MS patients receiving different doses of rituximab, the treatment was generally well-tolerated, with a low incidence of serious side effects, and was effective in controlling relapses.44

Rituximab is given by intravenous infusion. A common dosing regimen is two intravenous infusions separated by 2 weeks, repeated every 6 months.

Side effects and risks include infusion reactions, infections (including opportunistic infections such as PML), allergic reactions, headache, fatigue and anemia. Rituximab is a pregnancy category C.

Hematopoietic stem cell transplantation (HSCT)

HSCT uses autologous, hematopoietic stem cells, derived from the bone marrow or blood, to repopulate the body’s immune cells and stop the inflammatory process that contributes to active relapsing MS. While the procedure varies somewhat depending on the medical center and doctors who are performing it, the essential steps include: outpatient chemotherapy by intravenous infusion for up to 10 days to stimulate the production of bone marrow stem cells and promote their release into the blood; storage of stem cells from the blood for future use; inpatient chemotherapy for up to 11 days to suppress the body’s immune cells; infusion of stored stem cells into the bloodstream; administration of antibiotics to combat infection; immune reconstitution completed within three to six months.
• In a multicenter, single-group phase 2 trial involving 24 patients with aggressive relapsing MS that had not responded to other therapies, investigators reported a 69.6 percent MS activity-free survival rate at three years following transplantation, with no relapses and no Gd-enhancing lesions or new T2 lesions on 314 MRI sequential scans over a median follow-up of 6.7 years (range 3.9-12.7 years). The rate of brain atrophy decreased to the level expected in healthy controls and 35 percent of patients had a sustained improvement in EDSS. One patient died of transplantation-related complications resulting in liver failure; one patient required intensive hospital care for severe liver complications; all participants developed fevers typically associated with infections.

• In a 5-year multi-center study, 25 people with active relapsing MS that had not been controlled by disease-modifying therapies underwent HSCT with high-dose immunosuppressive therapy. After five years, 69 percent of participants remained free of disease activity and required no disease-modifying therapy. Reported side effects included blood cell reductions and infections.

• Other studies using a low-intensity lympho-ablative regimen or a non-myeloablative regimen designed to reduce toxicity, demonstrated some improvement in some trial participants, with fewer adverse events, leading investigators to conclude that these techniques may not be optimal for individuals with highly aggressive disease or disease of long-standing.

Scolding and colleagues, on behalf of the attendees at the International Conference on Cell-Based Therapies for Multiple Sclerosis, concluded the following based on their review of I/AHSCT (Immunoablation followed by autologous hematopoietic stem cell transplantation) studies:

• The available evidence suggests substantial efficacy in suppressing inflammatory disease activity; however, the benefit/risk/cost profile is not completely known.

• Patients most likely to benefit include those with active relapsing-remitting MS, <50 years of age, with <5 years disease duration, who are ambulatory and have ongoing disease despite disease-modifying therapy.

• Additional study is needed, particularly head-to-head comparisons with high efficacy disease-modifying agents.

• If HSCT is performed in clinical practice, safety and efficacy data should be collected, reported and published. However, the group strongly encouraged enrolling patients in ongoing clinical trials when available.

THE MULTIPLE SCLEROSIS COALITION

The Multiple Sclerosis Coalition (MSC) was founded in 2005 by three independent multiple sclerosis organizations in an effort to work together to benefit individuals with MS. Since that time, the MSC has grown to nine member organizations, all of whom provide critical MS programs and services.

Vision: To improve the quality of life for those affected by MS through a collaborative national network of independent MS organizations.

Mission: To increase opportunities for cooperation and provide greater opportunity to leverage the effective use of resources for the benefit of the MS community.

The primary objectives of the MSC are to educate, advocate, collaborate and improve the efficiency of services for individuals with MS and those who are close to them. With so much on the horizon in terms of MS research, treatments, advocacy and symptom management, the MSC provides critical momentum to work together to enhance these exciting MS initiatives and to ensure this collective support continues.

Members:

Accelerated Cure Project for Multiple Sclerosis (ACP)
Accelerated Cure Project is a national nonprofit dedicated to curing MS by determining its causes. Our repository contains samples and data from people with MS and other demyelinating diseases. Samples are available to researchers who submit all data they generate back to the repository to be shared with others.
acceleratedcure.org | 781-487-0008

Can Do Multiple Sclerosis (Can Do MS)
As a national nonprofit organization, Can Do Multiple Sclerosis is a leading provider of innovative lifestyle empowerment programs that empower people with MS and their support partners to transform and improve their quality of life.
mscando.org | 800-367-3101

Consortium of Multiple Sclerosis Centers (CMSC)
The Consortium of MS Centers is the preeminent North American organization of MS healthcare professionals and researchers with a network of more than 11,000 healthcare clinicians and scientists committed to MS care. CMSC promotes sustained improvements in MS healthcare practice through clinical research, education and training, networking and targeted advocacy efforts.
msscare.org | 201-487-1050

International Organization of Multiple Sclerosis Nurses (IOMSN)
The International Organization of Multiple sclerosis Nurses is the first and only international organization focused solely on the needs and goals of professional nurses, anywhere in the world, who care for people with multiple sclerosis. Mentoring, educating, networking, sharing – the IOMSN supports nurses in their continuing effort to offer HOPE.
iomsn.org | 201-487-1050

Multiple Sclerosis Association of America (MSAA)
The Multiple Sclerosis Association of America is a leading resource for the entire MS community, improving lives today through vital services and support. MSAA provides free programs and services, such as: a helpline; award-winning publications; website featuring educational videos and research updates; shared-management tools to assist the MS community in managing their MS; safety and
mobility equipment; cooling accessories for heat-sensitive individuals; educational events and activities; MRI funding and insurance advocacy; as well as other services.

mymsaa.org | 800-532-7667

Multiple Sclerosis Foundation (MSFocus)
The Multiple Sclerosis Foundation, known in the MS community as MS Focus, is a nonprofit organization focused on providing free services that address the critical needs of people with MS and their families and on helping them maintain the best quality of life. MS presents physical, emotional, and financial challenges families must face. MS Focus is here to provide the support, education, and assistance needed to adapt to these challenging circumstances. Our primary focus is on providing individuals with MS the help they need to maintain their health and well-being, to continue to be productive and independent, and to keep a roof over their heads and a safe environment in their home.

msfocus.org | 800-225-6495

National Multiple Sclerosis Society
The National MS Society mobilizes people and resources so that everyone affected by multiple sclerosis can live their best lives as we stop MS in its tracks, restore what has been lost and end MS forever.
nationalMSsociety.org | 800-344-4867

United Spinal Association
The United Spinal Association is a national VA-authorized non-profit organization committed to providing service programs and advocacy for those living with spinal cord injuries and disorders (SCI/D) such as multiple sclerosis, amyotrophic lateral sclerosis, and spina bifida. There are more than a million individuals throughout the country with SCI/D to whom the Association’s work is dedicated. The United Spinal Association has close to 40,000 members, 30 chapters, close to 200 support groups nationwide and publishes the New Mobility and Life Action magazines. Throughout its history, United Spinal Association has devoted its energies, talents and programs to improving the quality of life for Americans with spinal cord injuries and disorders.
